literature. Dermatologists should be aware of this entity and be able to diagnose it as part of the multidisciplinary management of the cutaneous side effects of new antineoplastic drugs, because managing these effects is important to ensuring adherence to treatment and optimizing the clinical response to therapy.

Eccrine Carcinoma: The role of Mohs Micrographic Surgery and Review of the Literature

Carcinoma ductal eccrine: papel de la cirugía de Mohs y revisión de la literatura

To the Editor:

Eccrine ductal carcinoma (EDC) is a rare adnexal neoplasm that arises from the eccrine glands. It accounts for 0.01% of all skin tumors.1 The classification of the adnexal tumors is complex and the nomenclature confusing.2 Traditionally, adnexal tumors have been considered to present an aggressive behavior.

We present the case of a 37-year-old man who was referred to our department for surgical excision of a well-defined, pink-colored tumor measuring 2.8 × 3 cm on the left cheek (Fig. 1A). The lesion, which had first appeared 2 years earlier, extended to deeper planes, and was diagnosed as an EDC. Soft-tissue ultrasound, magnetic resonance imaging, and positron emission tomography were performed and

**Figure 1** A, Clinical image of the lesion on the left cheek. The tumor measures 3 × 2.5 cm, has a pink surface, and shows signs of extension to deeper planes. B, Clinical image. Surgical excision of the tumor and design of the first stage of Mohs micrographic surgery (5 mm).
showed no deep involvement or distant spread. The excision of the lesion was extended to the muscle plane and a stage of Mohs micrographic surgery was performed for routine processing (Fig. 1B). Histology of the surgical specimen showed an intensely sclerotic epithelial tumor that infiltrated to the muscle (Fig. 2A). Structures with a ductal appearance and areas of squamous differentiation were observed within the tumor (Fig. 2B). Immunohistochemistry was positive for low molecular weight (Fig. 2C) and high molecular weight (Fig. 2D) cytokeratins and CD10 (Fig. 2E), and the cell proliferation index was low (Fig. 2F). No tumor nests were detected in the specimen sent for routine study. Surgical reconstruction was performed in a second operation using a rotation flap from the cheek and a Burow graft.
Although others have analyzed margins, although isolated and sometimes analyzed, others have recommended a margin size of 1 cm.

**EDC** is the most common type of adnexal tumor arising from the eccrine glands and is included in the group of tumors of uncertain behavior. Because of the small number of cases published, the prognosis remains unknown; the tumor appears to be locally aggressive but with a low probability of metastatic spread. Avraham et al. analyzed more than 200 adnexal tumors with eccrine differentiation, and the majority were found to be in stage I. Clinically, these are slow-growing, erythematous-violaceous tumors that may ulcerate. The clinical and histological differential diagnosis is broad. EDCs are more common in middle-aged and older men and arise preferentially on the scalp, trunk, and limbs.

The clinical differential diagnosis includes basal cell carcinoma, squamous cell carcinoma, skin metastases, cutaneous lymphomas, and amelanotic melanoma. The diagnosis is histological. The architecture of these tumors resembles that of ductal carcinoma of the breast, with nests and cords of cells, a variable degree of glandular differentiation, and infiltration of the adjacent tissues. EDCs typically stain positive for carcinoembryonic antigen, epithelial membrane antigen, and cytokeratins 5/6. Isolated cases with squamous differentiation have been reported; the origin of these tumors is controversial and it has been suggested that they may be squamous cell carcinomas arising in the tubules. This confusion is probably due to the complexity of their diagnosis, which will have led to underdiagnosis. The histological differential diagnosis includes other adnexal tumors, squamous cell carcinoma in those cases with extensive squamous differentiation, and a possible collision between squamous cell carcinoma and EDC.

Imaging studies for staging have not been standardized, although screening for local invasion and distant spread is recommended. Because EDC is such a rare tumor, it has been included in the TNM staging for squamous cell carcinoma.

Recommended treatment is by surgical excision of the tumor with negative margins, either by radical surgical excision or using Mohs micrographic surgery. Although margin width has not been defined, margins should be broad because of the tendency to underestimate the size of the tumor. Margins between 1 and 2 cm have been sought in the majority of cases. Mohs micrographic surgery has been used with good results in other adnexal tumors, although reports have not specified whether fresh-tissue or fixed-tissue techniques were used. Some authors use 2 mm layers of resection, others use 5 mm, and some even support...
excising an additional layer after obtaining a tumor-free result.\textsuperscript{10} Comparing the 2 techniques, no local recurrences have been detected in the few cases treated by Mohs micrographic surgery, whereas recurrence rates of up to 70% have been reported after wide surgical excision,\textsuperscript{7} although the follow-up periods have been short. With respect to adjuvant treatment, these tumors have been shown to respond poorly to radiation therapy\textsuperscript{8} and chemotherapy. Adjuvant radiation therapy has not been shown to increase survival.

In conclusion, EDC is probably a less aggressive tumor than has been thought, but local recurrence is common. The squamous variant appears to be more common than has been reported in the literature and is probably underdiagnosed. In our opinion, Mohs micrographic surgery is a good therapeutic option for EDC, but diagnostic-therapeutic algorithms still need to be developed.

Allergic Contact Dermatitis Due to \textit{Dittrichia viscosa}\textsuperscript{\textcopyright}

Dermatitis alérgica de contacto por \textit{Dittrichia viscosa}

To the Editor:

Plant-induced allergic contact dermatitis (ACD) is a common disorder that can arise in numerous situations and places during daily life.\textsuperscript{1} Diagnosis is often challenging due to our lack of experience in its management.

We present the case of a 51-year-old woman with a long-standing history of rheumatoid arthritis on treatment with leflunomide. She consulted for an outbreak of pruritic lesions that had arisen 2 days earlier on her hands. Two weeks earlier she had developed lesions of similar characteristics that had resolved within a few days, after the application of topical corticosteroids. She stated that for the previous 2 months she had been applying an infusion of a plant called yellow fleabane (also known as sticky fleabane or false yellowhead) (Fig. 1) once a week to her hands to control pain. She prepared the infusion at home. Examination revealed multiple vesiculobullous lesions with a blood-stained content on a background of normal skin on the dorsum, palms, and fingers of both hands; in addition, she had desquamating erythematous plaques on both wrists (Fig. 2). Treatment with oral and topical corticosteroids and discontinuation of the application of the infusion led to complete resolution of the lesions and there have been no recurrences. The unknown irritant capacity of the plant led us to perform semi-open patch testing, applying fragments of the plant (stem, leaf, and flower) to the patient’s forearm, covering the samples with porous tape and removing them after an hour. At 48 hours, 2+ positive reactions were observed in the area of application of the leaf and stalk, with reactivation of the lesions previously present on the hands; these manifestations started to appear 24 hours after performing the test. Control tests were performed on 10 healthy patients using the same technique with dry leaves and stalks, with negative results. Patch testing was also performed with the standard series of the Spanish Contact Dermatitis and Skin Allergy Research Group (GEIDAC), the Martitior plant series, and the infusion of yellow fleabane in water. A 2+ positive reaction to the infusion of the plant was observed at 48 and 96 hours. All patch testing was performed in accordance with the criteria of the International Contact Dermatitis Research Group.
